(54) Title: NON WOVEN TEXTILE STRUCTURE INCORPORATING STABILIZED FILAMENT ASSEMBLIES

(57) Abstract

A plurality of substantially parallel continuous filaments, e.g. of cellulose acetate or rayon, and preferably newly formed, are consolidated or partially stabilised, e.g. by application of solvent and pressure, by hydroentanglement, by embossing, or by crimping and stretching. The filament assembly or subassemblies thus produced are further stabilised by folding, bundling, twisting or intertwining, e.g. to form braids (10), and are then bonded to a carrier layer or sandwiched between outer layers (12, 14), e.g. by hydroentanglement, melt blowing, spinbonding etc. The stabilised filament assemblies may be arranged spaced transversely and may be cut just prior to bonding so as also to provide longitudinally spaced three dimensionally thicker regions, ready for conversion to finished products such as absorbant feminine hygiene products or medical swabs or the like.

Non Woven Textile Structure Incorporating Stabilized Filament Assemblies

The present invention relates to non-woven textile materials and in particular to non-woven absorbent textile materials.

The present invention has particular application to absorbent textile materials or structures for uses in the field of sanitary protection, infant care and adult incontinence protection and also in the medical field, for example in or as dressings, swabs and laparotomy sponges. Further uses where absorbency may not be a critical factor e.g. as supports are equally applicable. These can include matrix materials for use in the production of tyres, conveyor material and other industrial and medical applications, such as orthopaedic padding.

Non-woven materials made by many different processes have been utilised as components over the years to produce absorbent materials for use in feminine hygiene, infant diapers and incontinence products. Modern technologies utilising fluff pulp non-woven structures often combined with other non-woven materials to form multilayer composite materials have been used to facilitate fluid capture, distribution and containment in such compositions. Other materials such as

-2-

superabsorbent polymers are often incorporated in these composites to maximise fluid containment.

WO 99/27876 and WO 99/30661 (SCA Hygiene Products AB) describe filament tows as a fluid acquisition materials in infant diapers and the like but as only one component in the absorbent matrices specified. More specifically, these specifications, both published in June 1999, disclose production of a layer of continuous tow filaments which may be of cellulose acetate, or of polyethylene, polypropylene, polyamide, polyester, polyvinyl acetate, viscose or rayon, or bi-component. Steps in production of said layer include crimping or curling, then stretching and distributing the tow filaments, then bonding same in a pattern of lines, spots or points by any suitable technique including thermal or ultrasonic bonding, calendering, laser or print-bonding or hydroentanglement. The filaments are cut to length either before or after the aforesaid bonding. Optionally the tow filaments can be bonded at the same time as the pattern of bonding mentioned above to a layer which can be a non-woven material. No further details are provided of the method of handling the tow filaments to produce a finished layer and it is believed that it would be impractical to deal with tow filaments direct from a bale in this manner.

One object of the present invention is to propose an improved manner of handling continuous filaments which would allow their incorporation into a finished product, or a part thereof for further assembly with other layers.

In accordance with one aspect of the present invention, a method of producing a non-woven textile structure is proposed which comprises the steps of a) initially consolidating a plurality of newly formed substantially parallel continuous filaments to provide a partially stabilized filament assembly, b) further constraining said filament assembly by, for example, folding, bundling, twisting or intertwining operations, and c) bonding or embedding the resulting constrained filament assembly to a carrier layer or layers.

Thus, the applicants believe it is impractical simply to crimp and stretch the continuous filaments and then to feed these directly into a bonding process. An intermediate step whereby the filament assembly is additionally stabilized is therefore considered necessary to achieve the two- or three-dimensional stability required in further composite production. This will impart the feel, bulk and other desirable attributes more normally associated with woven products in the final structure.

The initial consolidation step may be accomplished by application of solvent and pressure, calendering, or by hydroentanglement, or by embossing, or by crimping, followed by an additional step of stretching the filament assembly.

The further stabilizing or constraining of the filament assembly may then be accomplished by several means; for example, by braiding or by winding it upon a conical mandrel, then removing it in wound configuration from the mandrel and folding it flat or by any other suitable method of folding, twisting or intertwining of the filaments, which are substantially parallel, but may be undulating or straight.

In respect of the finished product, where the filament material is designed to serve as an absorbent core, significant improvements in fluid management, notably wicking and fluid containment are apparent over existing materials currently utilised and known to those skilled in the art.

Whilst any polymer filament system which can be rendered hydrophilic can be considered usable in this proposal, either alone or with other polymers to form blended filament assemblies, the preferred polymer is cellulose acetate which, in parallel-filament format, and stabilized to maintain integrity and performance, achieves outstanding fluid take up and wicking properties.

This performance can be optimised by the careful selection of filament diameters in the filament assemblies either as intimate blends or as arrays of coarser and finer filaments since interfilament space is required for fluid take up but finer spaces between the filaments are needed to provide the necessary capillary systems to optimise fluid wicking and containment as can be deduced from the Lucas-Washburn Equation and derivatives of this. The use of shaped cross sectional filaments is advantageous, many shapes being possible including but not limited to Y shaped filaments, stellar shaped filaments and the like. In these cases the crevices running along the shaped filaments act like fine capillary structures thus enhancing fluid wicking and full utilisation of the composite structures.

Cellulose acetate has been frequently used in non-woven fabrics in the past and reported in literature by Celanese Acetate, LIC and other sources such as Kimberly-

Clark but such non-woven materials have been conventional web-like structures based on staple fibres without the use of stabilized filament assemblies.

In order to provide processability, integrity, optimum fluid performance and importantly, physical three dimensionality and optimised conformability, it is necessary to pre-stabilize the filament assemblies prior to their further stabilization and subsequent introduction into non-woven structures. This can be achieved by a variety of routes dependent on the physical properties of the polymer system utilised. With the preferred polymer filaments made from cellulose acetate, methods include special fibre crimping which avoids creasing and capillary blockage, in-situ hydroentangling of the filaments to provide controlled inter-filament coherence, heat treatment, specialist moist ultra-sonic treatment, short term solvent application and withdrawal to form limited interfilament consolidation, embossing or a combination of the above technologies. This stabilization provides controlled inter-filament packing densities, vital to provide optimum fluid management in these filament assemblies. Dependent on the filament size and cross-sectional shape such densities will be very different to give this optimum fluid management. The further stabilization process has to be taken into account in optimizing these pre-stabilized filament formats since dimensional changes are possible in this further stabilization.

Although cellulose acetate is the preferred polymer for use in the filament assemblies claimed, other polymers are equally suitable. These can comprise viscose or solvent-spun rayons, polyesters, polypropylenes, and any filament-forming material which

can exhibit similar properties. To provide good fluid management, hydrophilic forms of any polymer are preferred.

The filaments are consolidated by methods appropriate to the chemistries of the polymers chosen for use. A particularly suitable polymer is solvent-spun rayon where the process of initial stabilisation can be achieved using a solvent process with N-methylmorpholine-N-oxide (NMMO). With other polymers such as the polyesters or polypropylenes, initial stabilization is best achieved by mechanical or thermal means.

In some cases, pre-stabilized filaments of one polymer type (e.g. cellulose acetate) may be combined with pre-stabilized filaments of another polymer type (e.g. solvent-spun rayon) in order to gain particular fluid management properties/advantages. In other instances, similar polymer type combinations may be used to gain other advantages such as improved tactile properties – in such cases blends of cellulose acetate filament assemblies may be combined with resilient filament assemblies of polyester or polypropylene.

Radio-opaque material may be incorporated in the filament assemblies to allow for usage in x-ray detectable sponges or other devices. Such radio-opaque polymers contain high percentages of barium sulphate which can be incorporated in the spinning dope prior to filament or possibly film extrusion. Filaments of radio-opaque material would be in very close proximity to one another in the fully-stabilized filament assemblies; the majority of these fully-stabilized filament assemblies being

free of the radio-opaque filaments. This is necessary to provide the required detection under x-ray conditions.

The non-woven technologies suitable for bonding such filament assemblies to a carrier layer of fibres, filaments or a non-woven material made from same, are many and varied and include the processes for blowing pulp fibres onto stabilized filament assemblies. The integrity of these assemblies may be enhanced in many cases by the incorporation of binding fibres, of which cellulose acetate is very appropriate (which can be optionally bicomponent fibres of different types such as sheath/core or side by side types for example) or related melt blown fibres (as seen in the Kimberly-Clark "COFORM" materials). In these incidences, a notorious shortcoming, inadequate fluid wicking, is overcome due to the presence of long filaments and controlled capillary structures without any tortuosity and wicking impedance seen in materials to date.

Melt blowing fibres onto stabilized filament assemblies provides for their controlled placement in non-woven structures, the melt blown fibres adhering to the upper surfaces and sides of these assemblies on deposition. By careful selection of the melt blowing polymer(s), elastomeric structures incorporating stabilized filament assemblies may be produced. Kimberly-Clark polyurethane based "Demique" systems are particularly suitable in this regard. Elastomeric structures provide for better conformability and in-use performance. Relevant melt blowing processes (onto shaped collection screens for example) to give three dimensional structures and other new melt blowing technologies known to those skilled in the art will also allow for a

flexible structure surrounding filament assemblies and again, stretchable conformable products containing positioned stabilized filaments.

Spunbonding polymer into filaments and the like and resultant web or webs can be utilised to lock stabilized filament assemblies into place. The bonding processes, notably thermal but also possibly ultrasonic or other means can be utilised to achieve this locking. With thermal bonding processes, best results with minimal distortion of the filament assemblies are attained by the use of a lower melting point polymer in the spunbond component and then adhering these spunbonded filaments by relevant techniques such as through air bonding or suitable calendering processes for example.

Calender or other thermal bonding techniques can be employed to incorporate a web on one side of the stabilized filament assemblies or on both sides. Ultrasonic bonding can also be utilised to achieve similar results. Such webs should preferably be receptive to thermal bonding or ultrasonic bonding as appropriate although the thermal or ultrasonic properties of appropriate filament assembly polymers can be utilised on thermally or ultrasonically inert non-woven materials provided that the intrinsic properties of the stabilized filament assemblies are not degraded. Of particular note are techniques to provide the enhanced bonding of cellulose acetate or other polymeric stabilized filaments whereby the presence of moisture or residual solvent as appropriate facilitates this bonding of filaments under calender bonding or ultrasonic bonding processes.

The through-air bonding or powder-bonding of fibres or filaments around stabilized filament assemblies results in fabrics with defined filament assembly positioning. Many such fabrics are lofty thus enhancing fluid take-up in absorbent structures, preferably when such fibres are hydrophilic or rendered hydrophilic.

Stabilized filament assemblies can alternatively be affixed to fibrous webs by controlled needle punching processes, the needle arrays being as designed to minimise damage to the stabilized filaments placed in arrays with the fibrous webs prior to the needling process. Longer fibres are strongly preferred in the webs prior to needling coupled with adequate cross-laying to ensure fibre "wrap round" of the positioned filament assemblies.

All the non-woven structures described can be laminated to suitable backing sheets either during manufacture or as an afterprocess to provide for extra security in use by preventing fluid leakage through the thickness of the absorbent composites. Such backing sheets include polymeric films, preferably those which feature water vapour permeability to optimize skin wellness in use. Preferred backing sheets such as, for example, those made from cellulose or cellulose acetate exhibit environmentally responsible disposability.

The use of stabilized filament assemblies provides the optimum matrix for fluid management and imparts the necessary three-dimensionality so important in these types of absorbent composite structures.

The non-woven materials as disclosed in this current invention are very suitable as a replacement for gauze, either woven or non-woven as used in medical dressings, sponges and laparotomy sponges. In particular, they can be highly absorbent and can possess a non-adherent surface, if hydrophobic outer materials are combined with the stabilized filament assemblies, without any loose lint, thus providing for good wound healing. Because of the high absorbency which can be achieved using these materials, there is no need for folding or use in multiple plies, as is the case with all woven and non-woven sponges to date. This allows for economy of use, since less material is involved, and further provides for shaped sponges which are difficult to produce when folding is involved.

The stabilized filament assemblies as described can be incorporated in final non-woven production in formats which give the final composites the feel and three-dimensionality of woven and non-woven plied structures. The texture, absorbency performance, and appearance of the final composites are dependent on the number, size and spacing of the stabilized filament assemblies incorporated in these composites. The stabilized filament assemblies provide the means for fluid management to give these finished composites the necessary absorbency which to date has only been obtained by plied structures.

The materials or structures described in this disclosure can be made into converted pieces with controlled stabilized filament deposition both in the longitudinal and cross directions giving free edges to these pieces with no stabilized filaments present. In other words, the stabilized filaments may be spaced apart transversely on a carrier

-11-

web, and cut at intervals as deposited and bonded so as to leave areas of carrier material around each island of stabilized filament assembly.

In this respect, it is possible to position the stabilized filament assemblies immediately prior to hydroentangling or other non-woven operations where the filament assemblies are incorporated in such a manner that the ends of these filament assemblies do not reach the edges of the finished products made from these composites. Where hydroentangling is used to produce the final composite materials, the stabilized filament assemblies can be cut and positioned prior to the passage of these assemblies through the hydroentangling process. By suitable processing it is then possible to cut out or otherwise separate the composites produced into finished product at the end of the hydroentangling process as an in-line process. Means to cut and position the stabilized filament assemblies are many and varied, and are well known to those skilled particularly in diaper manufacturing technology.

Although all the examples cited relate to absorbent materials, it is equally valid that such stabilized filament technology can be utilised to produce non-woven fabrics with unique physical properties, notably controlled strength without the problems of "necking" due to the Poisson's Ratio effect and hence rendering such materials suitable to a wide range of industrial and other applications where absorbency might not be a critical factor or be in fact necessary.

The invention will be exemplified by reference to the accompanying drawings, in which;

Figure 16 is a sketch illustrating another method of forming a nonwoven composite in accordance with the invention, and

Figure 17 is a sketch illustrating another nonwoven composite structure in accordance with the invention.

Figure 1 is a diagrammatic representation illustrating the formation of a pre-stabilized filament assembly as part of the solvent-spinning of cellulose acetate.. Filaments (63) of cellulose acetate in acetone emanate from the spinneret system (64) and pass through nip rollers (65) where the residual acetone content present in the filaments causes their partial bonding, thus producing a filament assembly which can be handled, and further processed to give fully-stabilized filament assemblies. The rollers (66) can be used to give some embossing to these filaments thus imparting further integrity if so desired.

Figure 2 illustrates diagrammatically parallel filaments (202) in this case produced from solvent spun rayon which are initially consolidated by the partial fusion of these filaments after their production. Points of fusion (201) can be observed to maintain the parallel assembly of the filaments (202) thus providing optimum fluid management. Similar effects are attainable from cast films or ribbons of solvent spun rayons.

Figures 3a and 3b illustrate diagrammatically how a mandrel system can be utilised to take two pre-stabilized filament assemblies (67, 68) and, by a process of rotation and drawing as indicated by the arrow, produce a fully-stabilized filament assembly (69) featuring a convoluted surface texture (70). After the wound assembly is drawn off

the mandrel, it is folded flat before incorporation and bonding to a carrier layer or between carrier layers.

Figures 4 and 5 illustrate two alternative practical embodiments of fully stabilized filament assemblies suitable for bonding to a carrier layer to produce material in accordance with the invention. In the case of Figure 4, pre-stabilized filament sub-assemblies (60) have been intertwined to form a flattened braid. In the case of Figure 5, two pre-stabilized filament sub-assemblies or bundles have been twisted or folded together to form a fully stabilized filament assembly (62) which can subsequently be incorporated into a nonwoven assembly, for example, by hydroentanglement.

With reference to Figures 6 and 7, a first practical embodiment of the material of the invention consists of an inner core of two longitudinally-orientated stabilized filament assemblies in the form of braids (10) sandwiched between, and laminated to, respective outer layers (12, 14) of compacted fibres.

The material is formed by a process of hydroentanglement, a known process whereby jets of water at high pressure are fired at both outer surfaces of the outer layers (12, 14) as the component webs (12, 14) and the braided filament assemblies (10) are passed around a series of rollers and/or guides in apparatus similar to that shown in Figure 8. In this respect, the braided filament assemblies (10) are simply fed between the respective fibre webs (12, 14) at the upstream end of the apparatus.

-16-

The illustrated braids (10) are each formed from three filament sub-assemblies which may be termed bundles or ribbons. These may be made from any filament-forming polymer. Suitable materials can comprise cellulose acetate, rayons, polyesters or polypropylenes or any other suitable polymers known to those schooled in the art. The filaments in these assemblies may optionally consist of, or include, hollow or shaped derivatives which can significantly enhance the fluid transport characteristics of the final material. The filament sub-assemblies (bundles or ribbons) may or may not be pre-stabilized, e.g in manners described in relation to Figures 1 and 2.

The precise form of the braided filament assemblies may vary in other embodiments from large and bulky to small and fine, from a flat form similar to shoelaces to circular cross section similar to fine cord. Hollow assemblies may be employed to enhance storage and/or transport of fluids. The number of filaments per sub-assembly and the number of sub-assemblies may vary in different specific embodiments. Also, in other embodiments, the number of longitudinal filament assemblies may vary from a single unit to many, arranged side by side.

The braided filament assemblies impart bulk and three-dimensional structure to the final nonwoven material, as is apparent from Figure 7.

In other embodiments, the braided filament assemblies may also be pre-treated, for instance, by thermal compression at intervals to impart added textural features – undulations and width variations – to the final material.

The outer layers (12, 14) may also be of any type of fibre. Suitable examples are polyester or polypropylene. In other embodiments, in place of fibre layers (12, 14), pre-formed nonwoven materials made of fibres or filaments may be used.

Radio-opaque material may be incorporated by one filament or strand of filaments in the fully-stabilized filament assemblies, being pre-impregnated with barium sulphate. Such strands and filaments are of greater bulk than non-impregnated filaments but their sinuous course in the fully-stabilized filament assembly is advantageous as this avoids formation of a ridge when the finished material is stored as a roll. Moreover, there is provided a characteristic shape which can readily be recognised upon examining x-rays for foreign body contamination.

Figure 8 shows apparatus in which three layers have already been brought together at Point A on the diagram from originally separate supply wheels (not shown) to form a composite web (30). The outer webs can be of any fibres or filamentary material and can be either hydrophilic, hydrophobic or a combination of these. The inner material comprises the filament assemblies as already outlined in previous figures. The composite web (30) passes around four main rollers (31 – 34) and the plurality of auxiliary guide rolls (35). Three endless belts (41 – 43) pass around several guide rolls (35) and support various sections of the three-layer composite web (30). As the web (30) passes around the first main roller (31), high-pressure jets of water are directed at one side thereof from three successive transverse rows of nozzles (36, 37, 38). The first set of nozzles (36) imparts moisture to the composite (30), while the second and third sets (37, 38) consolidate the composite web (30) and begin the

-18-

process of tangling together the fibres and/or filaments at the interfaces between the original three separate layers. Further, high-pressure jets of water are directed at the other surface of the web (30) by rows of nozzles (39) as it passes around the second main roller (32). Yet further jets of water from respective sets of nozzles (44, 45) impinge on the respective surfaces of the web (30) as it passes around the third and fourth main rollers (33, 34). The unitary laminate material then emerges at Point B.

Figure 9 shows how water may be directed at at least one of the respective outer webs of fibres or filaments at a plurality of different angles. Nozzles (49), particularly those near the beginning of the hydroentanglement process corresponding to nozzles such as (37, 38 or 39) in Figure 8, are mounted upon a bridge structure (50) so that some direct water at the web (30) at an angle. This water directed at an angle causes preferentially binding at the edges of spaced apart stabilized filament assemblies thus holding them securely in position.

Figure 10a illustrates diagrammatically two different forms of fully stabilized filament assemblies (71, 72) bonded to a single layer (73) of nonwoven fabric.

Filament assembly (72) is twisted. Figures 10b and 10c show how these stabilized filament assemblies (172) possibly similar to (72) in figure 10a are bonded between two outer carrier layers (170, 171).

Figure 11 illustrates diagrammatically a means by which pre-stabilized filament assemblies (74) can be further stabilized by in-situ hydroentanglement (75) and

drying (76) to form fully stabilized filament assemblies (77). This process is not to be confused with that described in Figure 8.

Figure 12 illustrates diagrammatically blown fluff pulp (78) which optionally could contain melt-blown fibres as seen in the Kimberly-Clark COFORM process deposited onto fully-stabilized filament assemblies (79) to produce an absorbent composite structure (80) eminently suitable for absorbent matrices for feminine hygiene, infant diapers and adult incontinence products.

Figure 13 illustrates diagrammatically fully-stabilized filament assemblies (81) surrounded by melt-blown fibres (82) to produce a bi-layered structure (83), again suitable for absorbent composites.

Figure 14 illustrates diagrammatically fully-stabilized filament assemblies (84) surrounded by two layers of spun-bonded nonwoven (85, 86) and subjected to thermal bonding by through-air technology (87) to produce a sandwich-type structure (88) suitable for absorbent composites.

Figure 15 illustrates diagrammatically fully-stabilized filament assemblies (89) surrounded by cross-laid fibrous fleeces (90, 91) and then subjected to needle punching in zones apart from these stabilized filament assemblies to prevent their damage and to give an integrated absorbent composite (92).

Figure 16 illustrates diagrammatically fully-stabilized filament assemblies (93) being laminated to water-vapour-permeable film (94) by ultrasonic technology (95) to produce a simple bi-layered structure (96) featuring excellent absorbency performance. This performance is enhanced particularly in feminine care applications if the film features a degree of flexibility in use.

Figure 17 illustrates diagrammatically one embodiment of a completed absorbent composite (97) according to the present invention with fibrous material (98) surrounding and controlling the placement of the fully-stabilized filament assemblies (99). In this instance, the fully-stabilized filament assemblies are completely enclosed with no edges being exposed at the periphery of the finished composite product.

Claims

1. A method of producing a non-woven textile structure comprising the steps of: consolidating a plurality of substantially parallel continuous filaments to provide a partially stabilized filament assembly, further constraining said filament assembly by a folding, bundling, twisting or intertwining operation, and bonding the resulting constrained filament assembly to a carrier layer.
2. A method according to claim 1 wherein the step of initial consolidation is accomplished by application of solvent and pressure.
3. A method according to claim 1 wherein the step of initial consolidation is accomplished by hydroentanglement.
4. A method according to claim 1 wherein the step of initial consolidation is accomplished by embossing.
5. A method according to claim 1 wherein the step of initial consolidation is accomplished by crimping, and is followed by an additional step of stretching the filament assembly.
6. A method according to any preceding claim wherein the step of further constraining the filament assembly is accomplished by braiding.

7. A method according to any preceding claim wherein the step of further constraining the filament assembly is accomplished by winding it upon a conical mandrel, then removing it in wound configuration from the mandrel and folding it flat.
8. A method according to any preceding claim wherein the filament assembly is bonded to the carrier layer by hydroentanglement.
9. A method according to claim 8 wherein the filament assembly is sandwiched between a carrier layer and a further layer and is bonded thereto by hydroentanglement.
10. A method according to any preceding claim wherein the filament assembly is cut at intervals prior to bonding to the carrier layer.
11. A non-woven textile structure produced according to the method of any preceding claim and comprising at least one stabilized filament assembly, composed of substantially parallel filaments, bonded to a carrier layer.
12. A structure according to claim 11 wherein an array of spaced, substantially parallel stabilized filament assemblies are bonded to the carrier layer.

13. A structure according to claim 11 or 12 wherein the filament assembly or assemblies is/are sandwiched between and bonded to the carrier layer and a further layer.
14. A structure according to claim 11 or 12 wherein the filament assembly or filament assemblies is/are embedded within the carrier layer.
15. A structure according to any of claims 11 to 14 wherein the carrier layer and the further layer, when present, comprises fibres or filaments or a non-woven material formed of fibres or filaments.
16. A structure according to any of claims 11 to 15 wherein the filament assembly or filament assemblies comprise cellulose acetate.
17. A structure according to any of claims 11 to 16 wherein the carrier layer, and the further layer when present, extend beyond the filament assembly or assemblies at the edges of the structure.
18. A structure according to any of claims 11 to 17 and having a three dimensional structure, i.e. a variation in thickness and/or defined surface contouring, which is visible or can be felt by hand.

19. A structure according to any of claims 11 to 18 whereby the, or each, filament assembly includes thermosetting filaments.
20. A structure according to any of claims 11 to 19 whereby the, or each, filament assembly includes radio-opaque material.
21. A structure according to any of claims 11 to 20 whereby the, or each, filament assembly comprises absorbent material.
22. A structure according to any of claims 11 to 21 in which the fibres of at least one of the carrier or further layers are hydrophobic or semi-hydrophobic.
23. A non-woven textile structure comprising a core of stabilized filament assemblies sandwiched between respective outer layers of fibres, or non-woven materials made from such fibres, and subjected to a process of hydroentanglement.
24. A structure according to claim 23 in which the stabilized filament assemblies are in the form of braids.
25. A structure according to claim 23 or 24 in which the stabilized filament assemblies comprise cellulose acetate.

# INTERNATIONAL SEARCH REPORT

Inter. Appl. Application No  
PCT/GB 00/01510

## A. CLASSIFICATION OF SUBJECT MATTER

IPC 7 D04H13/00 D02G1/00 D02G3/00 B32B5/26 D04H3/04  
D04H3/07 D04H3/10 D04H3/14

According to International Patent Classification (IPC) or to both national classification and IPC

## B. FIELDS SEARCHED

Minimum documentation searched (classification system followed by classification symbols)

IPC 7 D04H D02G B32B

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practical, search terms used)

EPO-Internal, WPI Data, PAJ

## C. DOCUMENTS CONSIDERED TO BE RELEVANT

Category *	Citation of document, with indication, where appropriate, of the relevant passages	Relevant to claim No.
X	GB 1 535 264 A (SOMMER EXPLOIT) 13 December 1978 (1978-12-13)  page 2, line 6 - line 15; figure 1 page 2, line 116 - page 3, line 7 page 2, line 78 - line 93; figures 2,3 ---	1,6, 11-15, 18,21
A	US 3 675 409 A (ROSENSTEIN NATHAN) 11 July 1972 (1972-07-11) column 2, line 39 - line 50; figure 2 ---	1
A	US 4 639 253 A (DYER JOHN ET AL) 27 January 1987 (1987-01-27) figures 5,6 --- -/--	11-20

Further documents are listed in the continuation of box C.

Patent family members are listed in annex.

### \* Special categories of cited documents :

- "A" document defining the general state of the art which is not considered to be of particular relevance
- "E" earlier document but published on or after the international filing date
- "L" document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)
- "O" document referring to an oral disclosure, use, exhibition or other means
- "P" document published prior to the international filing date but later than the priority date claimed

- "T" later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention
- "X" document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone
- "Y" document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art.
- "&" document member of the same patent family

Date of the actual completion of the international search

1 August 2000

Date of mailing of the international search report

10/08/2000

Name and mailing address of the ISA

[Continued on next page]

(54) Title: **NON WOVEN TEXTILE STRUCTURE INCORPORATING STABILIZED FILAMENT ASSEMBLIES**

(57) Abstract: A plurality of substantially parallel continuous filaments, e.g. of cellulose acetate or rayon, and preferably newly formed, are consolidated or partially stabilised, e.g. by application of solvent and pressure, by hydroentanglement, by embossing, or by crimping and stretching. The filament assembly or subassemblies thus produced are further stabilised by folding, bundling, twisting or intertwining, e.g. to form braids (10), and are then bonded to a carrier layer or sandwiched between outer layers (12, 14), e.g. by hydroentanglement, melt blowing, spinbonding etc. The stabilised filament assemblies may be arranged spaced transversely and may be cut just prior to bonding so as also to provide longitudinally spaced three dimensionally thicker regions, ready for conversion to finished products such as absorbant feminine hygiene products or medical swabs or the like.
